## ABSTRACT

Shah, Kavit Master, Purdue University, December 2014. Secure data aggregation scheme for sensor networks. Major Professor: Dr. Brian King.

This is the abstract.

## 1. INTRODUCTION

## 2. SENSOR NETWORKS BACKGROUND

Sensor networks are becoming ubiquitous in our day to day life. They are known also known as Internet of Things. In the following sections we show the applications and the rise of sensor networks. Then we describe why doing security in the sensor network presents the number of unique challenges and solutions to tackle those challenges.

### 2.1 Sensor Networks and Applications

In sensor networks, thousands of sensor nodes may interact with the physical environment and collectively monitor an area, generating a large amount of data to be transmitted and reasoned about. With the recent advances in sensor network research, we can use tiny and cheap sensor nodes to obtain a lot of useful information about physical environment. For example, we can use them to discover temperature, humidity, water quality, lightning condition, pressure, noise level, carbon dioxide level, oxygen level, soil moisture, magnetic field, characteristics of objects such as speed, direction, and size, the presence or absence of certain kinds of objects, and all kinds of values about machinery like mechanical stress level or movement [1]. These versatile types of sensors, allow us to use sensor network in a wide variety of scenarios. For example, sensor networks are used in habitat and environment monitoring, health care, military surveillance, industrial machinery surveillance, home automation, scientific data collection, emergency fire alarm systems, traffic monitoring, wildfire tracking, wildlife monitoring and many other applications.

**Military Application** Sensor networks can be used for enemy tracking, battlefield surveillance or target classification [2]. For example, *Palo Alto Research Center* tries to spot “interesting” vehicles (the vehicles marked specially) using motes equipped with microphones or steerable cameras [3]. The objective is to coordinate a number

of this kind of sensors in order to keep sensing the track of a chosen moving object minimizing any information gaps about the track that may occur.

**Environmental Monitoring** For example, *Meteorology and Hydrology in Yosemite National Park* [4], a sensor network was deployed to monitor the water system across and within the Sierra Nevada, especially regarding natural climate fluctuation, global warming, and the growing needs of water consumers. Research of the water system in the Sierra Nevada is difficult, because of its geographical structure. And sensor networks can be real blessing in such situation as they can operate with little or no human intervention.

**Health Care** Sensors can be used to monitor the patients round the clock. The most important criteria for the such networks are security and reliability. *CodeBlue* [5] is a system to enhance emergency medical care with the goal to have a seamless patient transfer between a disaster area and a hospital.

**Sustainable Mobility** With the driver less cars from companies like Google, connected and coordinated vehicles seems the future of transportation. Autonomous vehicle systems [6] describes how various various technologies in addition to the sensor networks is used in making sustainable mobility.

The application of a sensor network usually determines the design of the sensor nodes and the design of the network itself. As far as we know, there is no general architecture for sensor networks. Therefore, developing a protocol for sensor networks can certainly be challenging.

## 2.2 Energy Consumption

The sensor network's lifetime can be maximized by minimizing the power consumption of the sensor node's radio module. To estimate the power consumption, we have to consider the communication and computation power consumption at each sensor node. The radio module energy dissipation depends on two main parameters [7]. The first is  $E_{elec}(J/b)$ , the energy dissipated to run the transmit or receive electronics.

The second is  $\varepsilon_{amp}(J/b \cdot m^2)$ , the energy dissipated by the transmit power amplifier to achieve an acceptable noise ratio  $E_b/N_o$  at the receiver. We assume the  $d^2$  energy loss for transmission between sensor nodes since the distances between sensors are relatively short [8]. To transmit a  $k$  - bit packet at distance  $d$ , the energy dissipated is:

$$E_{tx}(k, d) = E_{elec} \cdot k + \varepsilon_{amp} \cdot k \cdot d^2 \quad (2.1)$$

and to receive the  $k$  - bit packet, the radio expends

$$E_{rx}(k) = E_{elec} \cdot k \quad (2.2)$$

For  $\mu Amp$  wireless sensor,  $E_{elec} = 50nJ/b$  and  $\varepsilon_{amp} = 100pJ/b \cdot m^2$ .

To sustain the sensor network for longer time all aspects of the sensor network should be efficient. For example, the networking algorithm for routing should be such that it minimizes the distance  $d$  between the nodes. The signal processing algorithm should be such that it process the networking packets with less computations. It is shown in [7] that by distributing the Fast Fourier Transform (FFT) algorithm in the network requires less communication between the sensor nodes. Also, for minimal energy dissipation, a processor should operate at the lowest voltage for a given clock frequency.

### 2.3 Data Aggregation

The sensor nodes in the network often have limited resources, such as computation power, memory, storage, communication capacity and most significantly, battery power. Furthermore, data communications between nodes consume a large portion of the total energy consumption. The in-network data aggregation reduces the energy consumption by aggregating the data before sending it to the parent node in the network which reduces the communications between nodes. For example, in-network data aggregation of the SUM function can be performed as follows. Each intermediate sensor node in the network forwards a single sensor reading containing the sum of all

the sensor readings from all of its descendants, rather than forwarding each descendants' sensor reading one at a time to the base station. It is shown that the energy savings achieved by in-network data aggregation are significant [9]. The in-network data aggregation approach requires the sensor nodes to do more computations. But studies have shown that transmitting the data requires more energy than computing the data. Hence, in-network data aggregation is an efficient and a widely used approach for saving bandwidth by doing less communications between sensor nodes and ultimately giving longer battery life to sensor nodes in the network.

We define the following terms to help us define the goals of in-network data aggregation approach.

**Definition 2.3.1** [10] ***Payload** is the part of the transmitted data which is the fundamental purpose of the transmission, to the exclusion of information sent with it such as meta data solely to facilitate the delivery.*

**Definition 2.3.2** ***Information rate** for a given node is the ratio of the payloads, number of payloads sent divided by the number of payloads received.*

The goal of the aggregation process is to achieve the lowest possible information-rate. In the following sections, we show that lowering information-rate makes the intermediate sensor nodes (aggregator) more powerful. Also, it makes aggregated payload more fragile and vulnerable to various security attacks.

## 2.4 Bandwidth Analysis

Congestion is a widely used parameter while doing bandwidth analysis of networking applications. The congestion for any given node is defined as follows:

$$Node\ congestion = Edge\ congestion \cdot Fanout \quad (2.3)$$

Congestion is a useful factor while analyzing sensor network as it measures how quickly the sensor nodes will exhaust their batteries [11]. Some nodes in the sensor

network have more congestion than the others, the highly congested nodes are the most important to the the network connectivity. For example, the nodes closer to the base station are essential for the network connectivity. The failure of the highly congested nodes may cause the sensor network to fail even though most of the nodes in the network are alive. Hence, it is desirable to have a lower congestion on the highly congested nodes even though it costs more congestion within the overall sensor network.

To distribute the congestion uniformly across the network, we can construct an aggregation protocol where each node transmits a single payload Defined in 2.3.1 to its parent in the aggregation tree. In this approach,  $\delta$  is dependent on the given aggregation tree. For example, an aggregation tree shown in Figure 2.1, with  $n$  nodes,

Fig. 2.1.: Star Network

organized in the star tree topology congestion is  $O(n)$ . And the network organized in the palm tree topology as shown in Figure 2.2 the congestion is  $O(1)$ . This approach can create some highly congested nodes in the aggregation tree which is undesirable. In most of the real world applications we cannot control  $\delta$  as the aggregation tree is random. Hence, it is desirable to have uniform distribution of congestion across the aggregation tree.

Fig. 2.2.: Palm Tree Network

## 2.5 Security in Sensor Networks

Here, we depict, what parameters should be taken into account while designing secure protocol for sensor networks. And how those parameters constrains protocol designer's choices of the protocol. Then we depict how data-aggregation can help overcome some of those limitation and some examples where security is ignored by making some strong network assumptions.

### 2.5.1 Physical Limitations

Sensor nodes are often deployed in open, hostile and unattended environments, so they are vulnerable to physical tampering due to the lower physical security. An adversary can obtain the confidential information from a compromised sensor and reprogram it with malicious software. The compromised node may then report an arbitrary false sensor readings to its parent node in the tree hierarchy, causing the

final aggregation result to far deviate from the true aggregate result. This attack becomes more damaging when multiple adversaries succeeds in injecting false data into the network which may cause catastrophic consequences [12].

### 2.5.2 Hardware Limitations

As far as we know, one of the first hardware platform for developing sensor network application is MICA [13] developed by University of Berkeley. Another popular platform is Mote from Intel [14]. Due to lower manufacturing cost of sensor nodes, they have low speed processor, limited storage, a short range trans receiver. For example, the major specifications for the latest ZigBee chip supporting IEEE 802.15.4 standard, CC2538 from TexasInstruments are shown in Table 2.1. This chip can do most of the security algorithms but has really little amount of memory storage. It has limited output power which constraints its transmission range which forces us to use multi-hop routing in the network as one node can not communicate with the node outside of its transmission range. This hardware limitations constrains protocol designer's choice of algorithms for applications.

### 2.5.3 Transmission Medium

In sensor networks, a group of sensor nodes ( or processors ) communicate over the radio (e.g., Bluetooth, WLAN). Traditionally, wireless medium has the issues of in synchronization, hidden station and expose station terminal problems, distributed arbitration, directional antennas, bandwidth limitations, higher error rate, security, scalability etcetera. For example, wireless network has approximately  $10^6$  times higher bit error rate (BER) than wired network which causes frequent link loss and then path loss. Hence, making unstable routing in the network. Higher BER creates higher collision rate in the network, generating higher overhead of retransmission and lowering the channel utilization and the throughput of the network. This kind of

	CC2538
Device Type	Wireless Micro controller
Frequency	2.4GHz
Processor Integration	ARM Cortex-M3

Security	AES-128/256; ECC-128/256; SHA2; RSA
RX Current	20 (mA)
Output Power	7 (dBm)
Data Rate(Max)	250 kbps
Type of Battery	AAA; AA; Rechargeable(Li-ION)

Table 2.1.: System-on-Chip specifications for IEEE 802.15.4 from TexasInstruments

transmission medium with constrained resources makes it challenging to design the secure data-aggregation protocol for sensor networks.

#### 2.5.4 Mobility

As we know, sensor nodes communicate via radio and the availability of the transmission medium changes over time due to link failure, bandwidth limitations or change in network topology. Nodes may be able to move, which further contributes to the instability of the communication link. The mobility issue makes difficult to do the routing in the network with the directional antennas in place. It also requires network to be agile enough to do the reconfiguration for the newer network topology. It impedes while doing the quality of service in the network. All these parameters combined contributes to making strong assumptions on the network topology while designing the secure data aggregation protocol for sensor networks.

### 2.5.5 In-network Data Aggregation

Designing secure data aggregation protocol for the wireless sensor network poses a numerous challenges due to resource limitations and inherent characteristics discussed in the previous subsections. One widely used approach to overcome the bandwidth limitation is to use in-network data aggregation. In-network data aggregation approach saves bandwidth by transmitting less payloads between sensor nodes. But that empowers an intermediate aggregate sensor nodes in the network by allowing it to control certain part of the network. For example, a malicious intermediate sensor node who does aggregation over all of its descendants payloads, needs to tamper with only one aggregated payload instead of tampering with all the payloads received from its descendants. Thus, a malicious intermediate sensor node needs to do less work to skew the final aggregated payload. An adversary controlling few sensor nodes in the network can cause the network to return unpredictable payloads, making an entire sensor network unreliable. Notice that the more descendants an intermediate sensor node has the more powerful it becomes.

Despite the fact that in-network aggregation makes an intermediate sensor nodes more powerful, some aggregation approaches requires strong network topology assumptions or honest behaviors from the sensor nodes. For example, in-network aggregation schemes in [11,15] assumes that all the sensor nodes in the network are honest. Secure Information Aggregation (SIA) of [16], provides security for the network topology with a single-aggregator model. Secure hierarchical in-network aggregation (SHIA) in sensor networks [17] presents the first and provably secure sensor network data aggregation protocol for general networks and multiple adversaries. We discuss the details of the protocol in the next chapter. SHIA limits the adversary's ability to tamper with the aggregation result with the tightest bound possible but it does not help detecting an adversary in the network. Also, we claim that same upper bound can be achieved with compact label format defined in the next chapter.

### 3. NETWORKING AND CRYPTOGRAPHY TOOLS

Here we describe the networking and cryptographic tools used in this protocol referred from [18, 19]. For example, we describe the Hash function, its properties and how it helps us achieve data integrity.

#### 3.1 Hash Function

A hash function takes a message as its input and outputs a fixed length message called hash code. The hash code represents a compact image of the message like a digital fingerprint. Hash functions are used to achieve data integrity.

A hash function  $h$  should have the following properties:

- Compression -  $h$  maps an input  $x$  of arbitrary finite bitlength, to an output  $h(x)$  of fixed bitlength  $n$ .
- Ease of computation - given  $h, x$  it is easy to compute  $h(x)$ .
- Preimage resistance - for all pre-specified outputs, it is computationally infeasible to find any input which hashes to that output, i.e., to find any preimage  $x'$  such that  $h(x') = y$  when given  $y$  for which a corresponding input is not known.
- 2nd-preimage resistance - it is computationally infeasible to find any second input which has the same output as any specified input, i.e, given  $x$ , to find a 2nd-preimage  $x' \neq x$  such that  $h(x') = h(x)$ .
- Collision resistance - it is computationally to find any two distinct inputs  $x, x'$  which hash to the same output, i.e., such that  $h(x) = h(x')$ .

We use SHA-256 [20] hash algorithm as a collision resistant hash function.

### 3.2 Digital Signatures

A digital signature is a mathematical scheme for demonstrating the authenticity of a digital message. A valid digital signature gives a recipient reason to believe that the message was created by a known sender, such that the sender cannot deny having sent the message (authentication and non-repudiation) and that the message was not altered in transit (integrity). A Digital Signature scheme consists of the following:

1. a plain text message space  $\mathcal{M}$  (set of strings over alphabets)
2. a signature space  $\mathcal{S}$  (set of possible signatures)
3. a signing key space  $\mathcal{K}$  (set of possible keys for signature generation) and a verification space  $\mathcal{K}'$  (a set of possible verification keys)
4. an efficient key generation algorithm  $\text{Gen} : N \rightarrow \mathcal{K} \times \mathcal{K}'$
5. an efficient signing algorithm  $\text{Sign} : \mathcal{M} \times \mathcal{K} \rightarrow \mathcal{S}$
6. an efficient verification algorithm  $\text{Verify} : \mathcal{S} \times \mathcal{M} \rightarrow \{\text{true}, \text{false}\}$

For any secret key  $s_k \in \mathcal{K}$  and any  $m \in \mathcal{M}$ , the message  $m$  is signed using key  $s_k$  as follows:

$$s = \text{Sign}_{s_k}(m) \quad (3.1)$$

For any  $s_k$  let  $p_k$  denote public key and for all  $m \in \mathcal{M}$  and  $s \in \mathcal{S}$ ,  $s$  as follows:

$$\text{Verify}_{p_k}(m, s) = \begin{cases} \text{true} & \text{with probability of 1} & \text{if } s = \text{Sign}_{s_k}(m) \\ \text{false} & \text{with overwhelming probability} & \text{if } s \neq \text{Sign}_{s_k}(m) \end{cases} \quad (3.2)$$

where the probability space is determined by the  $\mathcal{M}, \mathcal{S}, \mathcal{K}, \mathcal{K}'$  and perhaps the signing and verification algorithms. The “overwhelming probability” for the signature scheme determines the probability that the scheme allows for a forgery. Note that the Digital Signature scheme satisfies the following requirements:

- Only the owner of the secret key can generate a valid signature.

- The digital signature is easily verified by other parties.
- The digital signature is not only tied to the signer but also to the message that is being signed.
- Digital signatures cannot be separated from the message and attached to another message.
- Digital signatures do not encrypt the message. However, if necessary, a signed message can be encrypted after it is signed.

The Figure 3.1 from [21], shows the steps for signing and verifying the hashed message. The message is hashed before its being signed to reduce the message size. If the

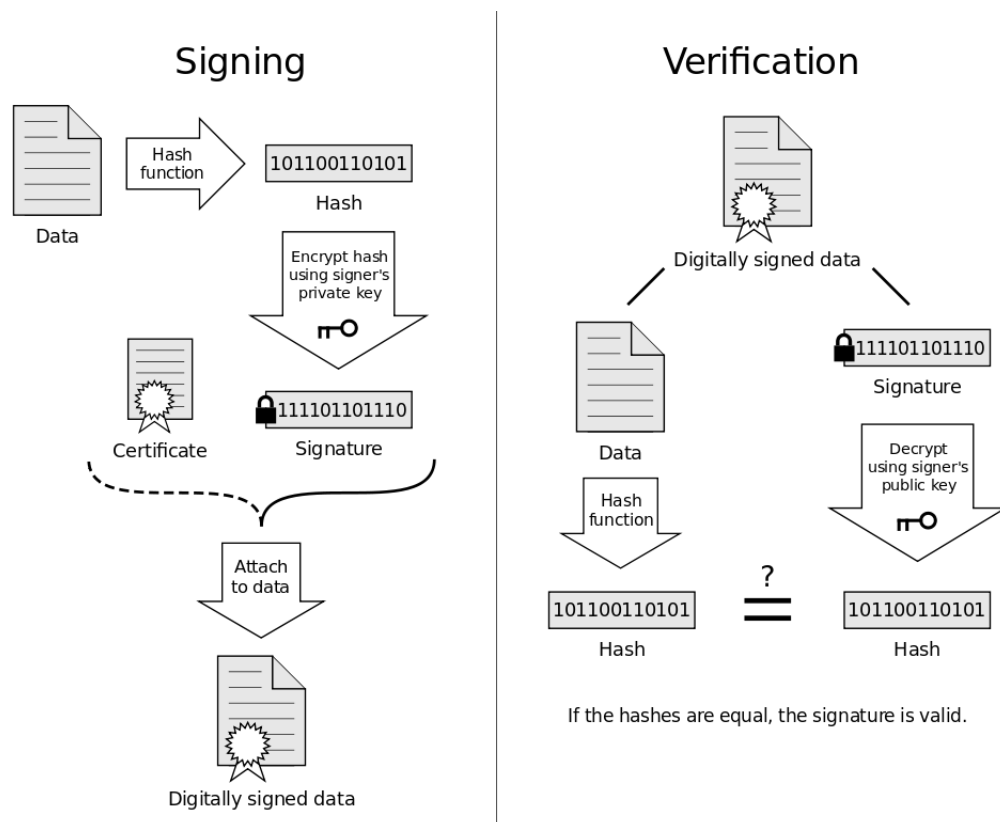

Fig. 3.1.: Signing and verification of digital signatures

message is not hashed before signing then the signature can be longer than the mes-

sage which is problematic for the longer messages. **Talk about non-repudiation, authenticity, integrity. Talk about similarities and differences between physical world signature non-repudiation, authenticity, integrity.** In physical world, your signatures are the same for all the messages. But this can not be possibly true for digital signatures as the attacker can obtain one signature and then use the same signature to pretend some one else.

### **3.4 XOR function**

### **3.5 Elliptic curve**

## 4. DATA AGGREGATION BACKGROUND

One of the fundamental and indispensable functionalities of sensor networks is the ability to answer queries over the data acquired by the sensors. For example, in Figure 4.1 the base station might be at the end of the river who initiates the query to the sensor network. And all the sensor nodes on both sides of the river has to response to the queries of the base station.

Fig. 4.1.: Routing River [22]

The resource constraints and security issues make designing mechanisms for information aggregation in large sensor networks particularly challenging.

Literature survey on data aggregation

talk about compression

lossy compression

lossless compression

data aggregation is lossy compression as there is no way the base station can know the original sensor readings

Hence, confidence in data is so important.

then talk about SHIA

## 5. DATA AGGREGATION WITHOUT INTERNAL VERIFICATION

Our work enhances Secure Hierarchical In-Network Data Aggregation (SHIA) protocol of [17] by making it communication efficient, adding new capabilities to the protocol, achieving similar security goals with non-resilient aggregation functions and efficient way of analyzing the protocol. In this chapter, we summarize the important parts of SHIA protocol and relevant terms, to build the foundation to describe our protocol in the following chapters.

SHIA computes the aggregate functions (such as *truncated SUM*, *AVERAGE*, *COUNT*,  $\Phi - QUANTILE$ ) of the sensor readings. For example, a network with 5 nodes having the following sensor readings 10, 11, 8, 15, 12 has the overall all sum of 56, the average of 11.2 and the median ( $\Phi = 0.5$ ) of 11. The goal of the SHIA is to compute the aggregate functions while assuming that partially a network is controlled by an adversary which is attempting to skew the final aggregated result.

### 5.1 Network Assumptions

We assume a multi hop network with a set  $S = \{s_1, \dots, s_n\}$  of  $n$  sensor nodes where all  $n$  nodes are alive and reachable. The network is organized in a rooted tree topology. The trusted base station resides outside of the network and has more computation, storage capacity than the sensor nodes in the network. **Note:** SHIA names the base station as the querier and the root of the tree as the base station. The base station knows total number of sensor nodes  $n$  in the network and the network topology. It also has the capacity to directly communicate with every sensor node in the network using authenticated broadcast. All the wireless communications between the nodes is peer-to-peer and we do not consider the local wireless broadcast.

Each sensor node has a unique identifier  $s$  and shares a unique secret symmetric key  $K_s$  with the base station. The keys enable message authentication, and encryption if the data confidentiality is required. All the sensor nodes are capable of doing symmetric key encryption and symmetric key decryption. They are also capable of computing collision resistant cryptographic hash function  $H$  (SHA-256) [20].

## 5.2 Attacker Model

We consider a model with a polynomially bounded adversary of [16], which has a complete control over some of the sensor nodes in the network. Most significantly, the adversary can change the measured values reported by sensor nodes under its control. An adversary can perform a wide variety of attacks. For example, an adversary could report fictitious values (probably completely independent of the measured reported values), instead of the real aggregate values and the base station receives the fictitious aggregated information. Since in many applications the information received by the base station provides a basis for critical decisions, false information could have ruinous consequences. However, we do not want to limit ourselves to just a few specific selected adversarial models. Instead, we assume that the adversary can misbehave in any arbitrary way, and the only limitations we put on the adversary are its computational resources (polynomial in terms of the security parameter) and the fraction of nodes that it can have control over. We focus on **stealthy attacks** [16], where the goal of an adversary is to make the base station accept false aggregation results, which are significantly different from the true results determined by the measured values, while not being detected by the base station. In this setting, denial-of-service (DoS) attacks such as not responding to the queries or always responding with negative acknowledgment at the end of verification phase clearly indicates to the base station that something is wrong in the network and therefore is not a stealthy attack. One of the security goals of SHIA is to detect the stealthy attacks. And one of the

security goals of our work is to detect an adversary who caused the stealthy attacks and remove it from the network to prevent these attacks in the future.

### 5.3 Resilient and Non-Resilient Aggregate Functions

Wagner [23] uses statistical estimation theory to quantify the effects of direct data injection on various aggregates functions. To understand Wagner's work we define following terms.

**Definition 5.3.1** *According to [17], each sensor node  $s_i$  has a data value  $a_i$  assuming that all the data values are non-negative bounded by real value  $a_i \in [0, r]$ , where  $r$  is the maximum allowed data value. The objective of the **aggregation process** is to compute some function  $f$  over all the data values, i.e.,  $f(a_1, \dots, a_n)$ .*

**Definition 5.3.2** *According to [17], a **direct data injection** attack occurs when an adversary modifies the data readings reported by the nodes under its direct control, under the constraint that only legal readings in  $[0, r]$  are reported.*

An **estimator** is an algorithm  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  where  $f(x_1, \dots, x_n)$  is intended as an estimate of some real valued function of  $\theta$ . We assume that  $\theta$  is real valued and that we wish to estimate  $\theta$  itself. Next, we define  $\hat{\Theta} := f(X_1, \dots, X_n)$ , where  $X_1, \dots, X_n$  are  $n$  random variables. We can define the root-mean-square(r.m.s) error (at  $\theta$ ):

$$rms(f) := \mathbb{E}[(\hat{\Theta} - \theta)^2 | \theta]^{1/2} \quad (5.1)$$

Wagner in [23] defines **resilient estimators and resilient aggregation** as follows. A  $k$ -node attack  $A$  is an algorithm that is allowed to change up to  $k$  of the values  $X_1, \dots, X_n$  before the estimator is applied. In particular, the attack  $A$  is specified by a function  $\tau_A : \mathbb{R}^n \rightarrow \mathbb{R}^n$  with the property that the vectors  $x$  and  $\tau_A(x)$  never differ at more than  $k$  positions. We can define the root mean square(r.m.s) error associated with  $A$  by

$$rms^*(f, A) := \mathbb{E}[(\hat{\Theta}^* - \theta)^2 | \theta]^{1/2} \quad (5.2)$$

where  $\hat{\Theta}^* := f(\tau_A(X_1, \dots, X_n))$ . To explain,  $\hat{\Theta}^*$  is a random variable that represents the aggregate calculated at the base station in the presence of the  $k$ -node attack  $A$ , and  $rms^*(f, A)$  is a measure of inaccuracy of the aggregate after  $A$ 's intrusion. If  $rms^*(f, A) \gg rms(f)$ , then the attack has succeeded in noticeably affecting the operation of the sensor network. If  $rms^*(f, A) \approx rms(f)$ , the attack had little or no effect. We define

$$rms^*(f, k) := \max\{rms^*(f, A) : A \text{ is a } k\text{-node attack}\} \quad (5.3)$$

so that  $rms^*(f, k)$  denotes the r.m.s. error of the most powerful  $k$ -node attack possible. Note that  $rms^*(f, 0) = rms(f)$ . We think of an aggregation function  $f$  as an instance of the resilient aggregation paradigm if  $rms^*(f, k)$  grows slowly as a function of  $k$ .

**Definition 5.3.3** According to [23], an aggregation function  $f$  is  $(k, \alpha)$ -**resilient** (with respect to a parameterized distribution  $p(X_i|\theta)$ ) if  $rms^*(f, k) \leq \alpha \cdot rms(f)$  for the estimator  $f$ .

The intuition is that the  $(k, \alpha)$ -resilient functions, for small values of  $\alpha$ , are the ones that can be computed meaningfully and securely in the presence of up to  $k$  compromised or malicious nodes. His work is summarized in the Table 5.1. According to this quantitative study measuring the effects of direct data injection on various aggregates, concludes that the **aggregates (truncated SUM and AVERAGE)** can be resilient under such attacks.

## 5.4 Security Goal

Without precise knowledge of application, the direct data injection attacks are indistinguishable from the malicious sensor readings. The goal of SHIA is to design an **optimally secure** aggregation algorithm with only **sublinear edge congestion**.

**Definition 5.4.1** According to [17], an aggregation algorithm is **optimally secure** if, by tampering with the aggregation process, an adversary is unable to induce the

Aggregate(f)	Security Level
minimum	insecure
maximum	insecure
sum	insecure
average	insecure
count	acceptable
$[l, u]$ -truncated average	problematic
5% -trimmed average	better
median	much better

Table 5.1.: Summary of Wagner's work

*base station to accept any aggregation result which is not already achievable by direct data injection.*

### 5.5 The SUM Aggregate Algorithm

In this algorithm, the aggregate function  $f$  is summation meaning that we want to compute  $a_1 + a_2 + \dots + a_n$ , where  $a_i$  is the sensed data value of the node  $i$ . This algorithm has three main phases:

- Query dissemination - initiates the aggregation process
- Aggregate commit - initiates the commitment tree generation process
- Result checking - initiates the distributed, interactive verification process

### 5.6 Query dissemination

Prior to this phase, an aggregation trees is created using a tree generation algorithm. We can use any tree generation algorithm as this protocol works on any

aggregation tree structure. For completeness of this protocol, one can use Tiny Aggregation Service (TaG) [9]. TaG uses broadcast message from the base station to initiate a tree generation. Each node selects its parent from whichever node it first receives the tree formation message. One possible aggregation tree for given network graph in Figure 5.1 is shown in Figure 5.2.

Fig. 5.1.: Network graph

To initiate the query dissemination phase, the base station broadcasts the query request message with the query nonce  $N$  in the aggregation tree. The query request message contains new query nonce  $N$  for each query to prevent replay attacks in the network. It is very important that the same nonce is never re-used by the base station. *SHIA* uses **hash chain** to generate new nonce for each query. A hash

chain is constructed by repeatedly evaluating a pre-image resistant hash function  $h$  on some initial random value, the final value (or “anchor value”) is preloaded on the nodes in the network. The base station uses the pre-image of the last used value as the nonce for the next broadcast. For example, if the last known value of the hash chain is  $h^i(X)$ , then the next broadcast uses  $h^{i-1}(X)$  as the nonce;  $X$  is the initial random value. When a node receives a new nonce  $N'$ , it verifies that  $N'$  is a precursor to the most recently received (and authenticated) nonce  $N$  on the hash chain, i.e.,  $h^i(N') = N$  for some  $i$  bounded by a fixed  $k$  of number of hash applications. A hash chain prevents an adversary from predicting the query nonce for future queries as it has to reverse the hash chain computation to get an acceptable pre-image.

Fig. 5.2.: Aggregation tree for network graph in Figure 5.1

## 5.7 Aggregate commit

The aggregate commit phase constructs cryptographic commitments to the data values and to the intermediate in-network aggregation operations. These commitments are then passed on to the base station by the root of an aggregation tree.

The base station then rebroadcasts the commitments to the sensor network using an authenticated broadcast so that the rest of the sensor nodes in the network can verify that their respective data values have been incorporated into the final aggregate value.

### 5.7.1 Aggregate commit: Naive Approach

In the naive approach, during aggregation process each sensor node computes a cryptographic hash of all its inputs (including its own data value). The aggregation result along with the hash value called a label, is then passed on to the parent in the aggregation tree. The label format is described in Definition 5.7.1. Figure 5.3 shows a commitment tree for the aggregation tree shown in Figure 5.2. Conceptually, a commitment tree is a logical tree built on top of an aggregation tree, with additional aggregate information attached to the nodes to help in the result checking phase.

**Definition 5.7.1** [17] *A commitment tree is a tree where each vertex has an associated label representing the data that is passed on to its parent. The labels have the following format:*

$$\langle \text{count}, \text{value}, \text{complement}, \text{commitment} \rangle$$

*Where count is the number of leaf vertices in the subtree rooted at this vertex; value is the SUM aggregate computed over all the leaves in the subtree; complement is the aggregate over the COMPLEMENT of the data values; and commitment is a cryptographic commitment.*

There is one leaf vertex  $u_s$  for each sensor node  $s$ , which we call the leaf vertex of  $s$ . The label of  $u_s$  consists of count = 1, value =  $a_s$  where  $a_s$  is the data value of  $s$ , complement =  $r - a_s$  where  $r$  is the upper bound on allowable data values, and commitment is the nodes unique ID.

Internal vertices represent aggregation operations, and have labels that are defined based on their children. Suppose an internal vertex has child vertices with the following labels:  $u_1, u_2, \dots, u_q$ , where  $u_i = \langle c_i, v_i, \bar{v}_i, h_i \rangle$ . Then the vertex has label  $\langle c,$

Fig. 5.3.: Naive commitment tree for Figure 5.2. For each sensor node  $s$ ,  $s_0$  is its leaf vertex, while  $s_1$  is the internal vertex representing the aggregate computation at  $s$  (if any). The labels of the vertices on the path of node  $I$  to the root are shown from Equation 5.4 to 5.8.

$v, \bar{v}, h$ , with  $c = \sum c_i$ ,  $v = \sum v_i$ ,  $\bar{v} = \sum \bar{v}_i$  and  $h = H[N||c||v||\bar{v}||u_1||u_2||\dots||u_q]$ .

The labels of the vertices of the commitment tree of Figure 5.3 are shown below.

$$I_0 = \langle 1, a_I, r - a_I, I \rangle \quad (5.4)$$

$$H_1 = \langle 2, v_{H_1}, r - v_{H_1}, H[N||2||v_{H_1}||\bar{v}_{H_1}||H_0||I_0] \rangle \quad (5.5)$$

$$B_1 = \langle 3, v_{B_1}, r - v_{B_1}, H[N||3||v_{B_1}||\bar{v}_{B_1}||B_0||E_0||F_0] \rangle \quad (5.6)$$

$$C_1 = \langle 4, v_{C_1}, r - v_{C_1}, H[N||4||v_{C_1}||\bar{v}_{C_1}||C_0||G_0||H_1] \rangle \quad (5.7)$$

$$A_1 = \langle 9, v_{A_1}, r - v_{A_1}, H[N||9||v_{A_1}||v_{A_1}^-||A_0||D_0||B_1||C_1] \rangle \quad (5.8)$$

The word vertices is used for the nodes in the commitment tree and the word node is used for the nodes in the aggregation tree. There is a mapping between the nodes in the aggregation tree and the vertices in the commitment tree, a vertex is a logical element in the commitment tree where as the node is a physical sensor node which does all the communications. The collision resistant hash function makes it impossible for an adversary to change the commitment structure once it is sent to the base station. Our payload format is compact than the label format which is discussed in the next chapter.

### 5.7.2 Aggregate commit: Improved approach

The aggregation tree is a subgraph of the network graph so it may be randomly unbalanced. This approach tries to separate the structure of the commitment tree from the structure of the aggregation tree. So, the commitment tree can be perfectly balanced.

In the naive approach, each sensor node always computes the aggregate sum of all its inputs which is a greedy approach. SHIA uses delayed aggregation approach, which performs an aggregation operation if and only if it results in a complete, binary commitment tree.

We now describe SHIA's delayed aggregation algorithm for producing balanced commitment trees. In the naive commitment tree, each sensor node passes to its parent a single message containing the label of the root vertex of its commitment subtree  $T_s$ . In the delayed aggregation algorithm, each sensor node passes on the labels of the root vertices of a set of commitment subtrees  $F = \{T_1, \dots, T_q\}$ . We call this set a commitment forest, and we enforce the condition that the trees in the forest must be complete binary trees, and no two trees have the same height. These constraints are enforced by continually combining equal-height trees into complete binary trees of greater height.

**Definition 5.7.2** [17] *A commitment forest is a set of complete binary commitment trees such that there is at most one commitment tree of any given height.*

The commitment forest is built as follows. Leaf sensor nodes in the aggregation tree originate a single-vertex commitment forest, which they then communicate to their parent sensor nodes. Each internal sensor node  $s$  originates a similar single-vertex commitment forest. In addition,  $s$  also receives commitment forests from each of its children. Sensor node  $s$  keeps track of which root vertices were received from which of its children. It then combines all the forests to form a new forest as follows. Suppose  $s$  wishes to combine  $q$  commitment forests  $F_1, \dots, F_q$ . Note that since all commitment trees are complete binary trees, tree heights can be determined by inspecting the count field of the root vertex. We let the intermediate result be  $F = F_1 \cup \dots \cup F_q$ , and repeat the following until no two trees are the same height in  $F$ . Let  $h$  be the smallest height such that more than one tree in  $F$  has height  $h$ . Find two commitment trees  $T_1$  and  $T_2$  of height  $h$  in  $F$ , and merge them into a tree of height  $h + 1$  by creating a new vertex that is the parent of both the roots of  $T_1$  and  $T_2$  according to the inductive rule in Definition 5.7.1.

**Example 5.7.1** *The commitment-forest generation process for node  $A$  of Figure 5.2 is shown here.*

$$\begin{aligned}
 A_0 &= \langle 1, a_A, r - a_A, A \rangle \\
 D_0 &= \langle 1, a_D, r - a_D, D \rangle \\
 E_0 &= \langle 1, a_E, r - a_E, E \rangle
 \end{aligned} \tag{5.9}$$

$$\begin{aligned}
 B_1 &= \langle 2, v_{B_1}, v_{B_1}^-, H(N|2||v_{B_1}||v_{B_1}^-||B_0||F_0) \rangle \\
 C_2 &= \langle 4, v_{C_2}, v_{C_2}^-, H(N|4||v_{C_2}||v_{C_2}^-||H_1||C_1) \rangle \\
 A_1 &= \langle 2, v_{A_1}, v_{A_1}^-, H(N|2||v_{A_1}||v_{A_1}^-||A_0||D_0) \rangle \\
 v_{A_1} &= a_A + a_D; v_{A_1}^- = r - a_A + r - a_D
 \end{aligned} \tag{5.10}$$

Fig. 5.4.:  $A$  receives  $C_2$  from  $C$ ,  $(B_1, B_0)$  from  $B$ ,  $D_0$  from  $D$  and generates  $A_0$ . The commitment forest received from a given sensor node is indicated by dashed-line box.

Fig. 5.5.: First Merge:  $A_1$  vertex created by  $A$ .

$$A_2 = \langle 4, v_{A_2}, v_{A_2}^-, H(N||4||v_{A_2}||v_{A_2}^-||B_1||A_1) \rangle \quad (5.11)$$

$$v_{A_2} = v_{A_1} + v_{B_1}; v_{A_2}^- = r - v_{A_1} + r - v_{B_1}$$

$$A_3 = \langle 8, v_{A_3}, v_{A_3}^-, H(N||8||v_{A_3}||v_{A_3}^-||C_2||A_2) \rangle \quad (5.12)$$

$$v_{A_3} = v_{A_2} + v_{C_2}; v_{A_3}^- = r - v_{A_2} + r - v_{C_2}$$

Fig. 5.6.: Second Merge:  $A_2$  vertex created by A.

Fig. 5.7.: Third Merge:  $A_3$  vertex created by A.

## 5.8 Result checking

SHIA presents novel distributed verification algorithm achieving provably optimal security while maintaining sublinear edge congestion. In our work, we take similar approach and add new capabilities to help find an adversary. Here, we describe the SHIA's result checking phase to build the basis for our work. The purpose of the result checking phase is to enable each sensor node  $s$  to independently verify that its data

value as was added into the SUM aggregate, and the complement ( $r - a_s$ ) of its data value was added into the COMPLEMENT aggregate. First, the aggregation results from the aggregation-commit phase are sent by the base station using authenticated broadcast to every sensor node in the network. Each sensor node then individually verifies that its contributions to the respective SUM and COMPLEMENT aggregates were indeed counted. If so, it sends an authentication code to the base station. The authentication code is also aggregated for communication efficiency. When the base station has received all the authentication codes, it is then able to verify that all sensor nodes have checked that their contribution to the aggregate has been correctly counted. The result checking process has the following phases.

**Dissemination of final commitment values.** Once the base station receives final commitment labels from the root of the commitment forest, it sends each of those commitment labels to the entire network using authenticated broadcast. Authenticated broadcast means that the each sensor node can verify that the message was sent by the base station and no one else.

**Dissemination of off-path values.** Each vertex must receive all of its off-path values to do the verification. The off-path values are defined as follows.

**Definition 5.8.1** [17] *The set of off-path vertices for a vertex  $u$  in a tree is the set of all the siblings of each of the vertices on the path from  $u$  to the root of the tree that  $u$  is in (the path is inclusive of  $u$ ).*

Vertex receives its off-path values from its parent. Each internal vertex has two children. For example, an internal vertex  $k$  has two children  $k_1, k_2$ .  $k$  sends the label of  $k_1$  to  $k_2$  and vice versa.  $k$  tags the relevant information of its left and right child. Once a vertex receives all of its off-path values it begins a verification phase.

**Verification of contribution.** The leaf vertex calculates the root vertex's label using its own label and off-path vertex labels. This allows the leaf to verify that its label was not modified on the path to the root during the aggregation-commit process. Then it compares the the calculated root vertex's label with the label received from the base station via authenticated broadcast. If those two labels match then it proceeds

Fig. 5.8.: Off-path vertices from  $u$  are highlighted in bold.

to the next step with ACK message or with NACK message.

**Collection of authentication codes.** Once each sensor node  $s$  does verification of contribution for its leaf vertex  $v_s$  it sends the relevant authentication code to the base station. The authentication code for sensor node  $s$  with ACK and NACK message has the following format.

$$MAC_{K_s}(N||ACK) \quad (5.13)$$

$$MAC_{K_s}(N||NACK) \quad (5.14)$$

Where ACK, NACK are unique message identifier for positive acknowledgment and negative acknowledgment respectively,  $N$  is the query nonce and  $K_s$  is secret key that  $s$  shares with the base station. Collection of authentication code starts with the leaf nodes in the aggregation tree. Leaf nodes in the aggregation tree send their authentication codes to their parent. Once the parent node has received the authentication from all of its children it does XOR operation on all the authentication codes including its own authentication code and sends it to its parent in the aggregation tree. Each internal sensor node  $s$  in the aggregation tree repeats the process. Finally,

the root of an aggregation tree sends a single authentication code to the base station which is an XOR of all the authentication codes of the aggregation tree.

**Verification of confirmations.** Since the base station knows the key  $K_s$  for each sensor node  $s$ , it verifies that every sensor node has released its authentication code by computing the XOR of the authentication codes for all the sensor nodes in the network, i.e.,  $\bigoplus_{i=1}^n MAC_{K_i}(N||ACK)$ . The base station then compares the computed code with the received code. If the two codes match, then the base station accepts the aggregation result.

**Theorem 5.8.1** [17] *Let the final SUM aggregate received by the base station be  $S$ . If the base station accepts  $S$ , then  $S_L \leq S \leq (S_L + \mu \cdot r)$  where  $S_L$  is the sum of the data values of all the legitimate nodes,  $\mu$  is the total number of malicious nodes, and  $r$  is the upper bound on the range of allowable values on each node.*

The above theorem is proven by SHIA. SHIA achieves security over the truncated SUM which is a resilient aggregator according to Wagner [23]. Our protocol works on SUM which is non-resilient aggregate and achieves the similar security goals.

## 6. DATA AGGREGATION WITH INTERNAL VERIFICATION

The most significant design aspect of the sensor network is the **lifetime of the network**. The sensor network tend to have limited life span as they are powered by the battery. The lifetime of the sensor network is inversely proportional to the sensor nodes' power consumption. One of the most dominating factor for the power consumption is transmitting and receiving the data between sensor nodes, making network bandwidth an expensive resource. The bandwidth is more expensive resource than the local data computation, as data computation consumes less power than transmitting or receiving the data. The obvious solution to increase the lifespan of the sensor network is to decrease the bandwidth usage in the network. Data aggregation techniques can reduce the bandwidth usage in the network. It can greatly increase the lifespan of the network. Hence, data-aggregation techniques are one of the key tool in our tool box while designing protocol for the sensor networks.

The second most significant factor in the design of the data aggregation protocol is **security**. In the perfect world, one desires the following security properties from the secure networking protocol.

**Confidentiality** - ensures that information is accessed only by authorized parties. It is also known as secrecy or privacy. Ensuring confidentiality can be difficult. For example, who determines which parties are authorized to access the information? By “accessing” information, do we mean that an authorized party can access a single bit? the whole collection? pieces of information out of context? Can someone who is authorized disclose that information to other parties? [24]

**Integrity** - assures that the only authorized entities can modify the information; where modification means writing, creating, deleting and changing the information. If one say one have preserved an integrity of the information one may mean different

things depending on the context. It can mean the following, one has preserved the information is precise, unmodified, modified only in acceptable ways by authorized parties or process. Error detection and correction are two important aspects of information integrity [24]. One important application of an integrity is when a user downloads any information from the web, the user wants to be assured that the information has not been altered in any way by the networking errors, by active attackers on the Internet or any other third party application.

**Availability** - means that information is accessible to authorized parties at appropriate times. In other words, if some person or system has legitimate access to a particular set of objects, that access should not be prevented. Availability applies to the information and services. For example, information or service is available can mean the following. It is present in the usable form. It has the enough capacity to meet the service need. It is making enough progress, and, if it is in wait mode, it has a bounded waiting time. There is timely response to our requests. Resources are allocated fairly so that some requests are not favored over the others. The service can be used easily and in its intended way. For this reason, availability is sometimes known by its opposite, denial of service [24].

**Authentication** - assures the origin of the information. There are two types of authentication that rises in cryptography: entity authentication and data-origin authentication [25]. The entity authentication is also known as identification which is concerned with proving the identity of the parties involved in a communication. Data-origin authentication focuses on tying the information about the origin of the data, such as the creator and time of creation, with the data.

**Non repudiation** - requires neither the sender nor the receiver can deny the transmission. This is very important in electronic commerce applications. where it is important that a consumer cannot deny the authorization of a purchase.

**Access Control** - restricts an access to the information. Login credentials and Locks are two analogues mechanism of access control.

As you can see, expectations from secure networking protocol are far-reaching. It is very ambitious for any system to have all the above mentioned security properties at the same time. For some applications, some of the security properties are not required as well. For instance, in a physical world when a person writes a letter in its own handwriting, he puts his own signature on the letter. When that letter reaches to the other end the receiving party can verify the integrity of the message. In this example, integrity is important but confidentiality is not. Because a postal service can read the letter if its not enclosed inside the cover. The similar is true in the world of Internet. When a client downloads a file from the File Server using Internet. A client can verify the integrity of the File using the checksum but client does not care about if somebody on the network sniffed his downloading activity. So, these are the two applications where integrity is important but confidentiality is not.

It is critical to find out which security properties are desired for the particular application. In practice, protocol designer finds out the most important security properties for the applications before designing the protocol.

For example, Wagner's work [23] describes the attacks on standard schemes for data aggregation and introduces the problem of securing aggregation in the presence of malicious or spoofed data. He proposes a mathematical theory of security for aggregation. The theory quantifies, in a principled way, the robustness of an aggregation operator against malicious data. It draws novel connections to statistical estimation theory and to the field of robust statistics. He identifies techniques for aggregation that provide robustness against attack. It provides helpful guidance to sensor network implementors or designers in selecting appropriate aggregate functions.

Secure Information Aggregation (SIA) [16] address the problem of how to enable secure information aggregation, such that the user accepts the data with high probability if the aggregated result is within a desired bound, but that the user detects cheating with high probability and rejects the result if it is outside of the bound. SIA provides statistical security under the assumption of a single-aggregator model. In the single-aggregator model, sensor nodes send their data to a single aggregator

node, which computes the aggregate and sends it to the base station. This form of aggregation reduces communications only on the link between the aggregator and the base station, and is not scalable to large multihop sensor deployments. SIA provides the probabilistic data-integrity under strong network assumptions.

Secure Hierarchical In-network Aggregation (SHIA) [17], in many ways enhances Secure Information Aggregation (SIA). SHIA presents the provably secure sensor network data aggregation protocol for general networks and multiple adversarial nodes, in compare to SIA which provides probabilistic security for a single aggregate network topology. SHIA limits the adversarys ability to manipulate the aggregation result with the tightest bound possible, with no knowledge of the distribution of sensor data values. SHIA provides data-integrity for any hierarchical sensor networks because of that it can detect malicious activity in the network.

Data-integrity is an essential security primitive for the data aggregation algorithm. Failing to provide data-integrity to an aggregate algorithm can change the final results drastically as shown in section XXX. We think detecting a malicious activity without tracing down the malicious node responsible for it of no value. To give an analogy with the physical world, it is like you know there is a crime and you can not do anything about it. Because that malicious node will continue doing malicious activity in the future, which first of all makes our integrated data garbage. And network has to redo the all the work to create response for the query from the base station, which consumes lot of bandwidth. Hence, we think detecting a malicious node who is responsible for the malicious activity is equally important. If we can track down the malicious node in the network then we can remove that node from the network for all future queries. And make sure that all the future queries are not manipulated by any malicious node in the network.

If we have to achieve all the security properties we can make each sensor node signs its sensor data and then send its data with its signature to its parent. And the network forwards all the data with their signatures to the base station. The base station verifies all the signatures and then calculates the aggregate function. Clearly,

this approach is not practical as it requires  $n$  signatures to traverse through the link between the base station and the root of the node of the network; where  $n$  is the number of nodes in the network.

We want to design a secure aggregation protocol which can be applied to any hierarchical sensor network which can **detect the malicious activity** (in terms of data aggregation) and can **detect the adversary** causing the malicious activity in the network. As we saw in the previous chapter SHIA can detect the malicious activity in the network with only sub-linear edge congestion. So, we built our work on top of SHIA which can detect an adversary.

To detect an adversary (or prove someone guilty), we need proof that the adversary is responsible for the malicious activity. To achieve our goal, we think the Digital signature is the perfect cryptographic tool. Consider the following example showing the analogy with the signature scheme in the physical world, used by the postal services. When a postman delivers the package, the receiving party has to sign the document informing that he verified and received the package. As only the receiving party can create his signature, in the future he can not claim of not receiving the package or receiving the damaged or incorrect package. And if he claims such, the postal company has the signed document as the proof mentioning that the package was received successfully, by the receiving party. The signed document also ensures to the postal company that the postman did not misplace or steal the package. The signature scheme used by the postal service promises authenticity (assures the origin of the message) and non repudiation (neither sender or receiver can deny the transmission). With Digital signatures one can achieve **non-deniability (non repudiation), authentication, integrity** (assures that only the authorized parties can modify the message) as described in Section 3.2.

We want to achieve this with the least amount of overhead in terms of bandwidth and computation power in the network. So, the protocol can be easily implemented in the real world sensor networks.

## 6.1 Design Goals

We develop the aggregation protocol which works for any random hierarchical sensor networks with a single or multiple adversaries. It works on the resilient as well as non-resilient aggregation functions Defined in 5.3.3, without compromising any desired security properties. It identifies all the adversaries in the network who are responsible for the malicious activity. It prevents masquerade attacks in the network so this protocol can easily be applied to do the voting scheme in the network.

We want to achieve all the mentioned goals by inducing only  $O(\delta \log^k n)$  node congestion in the aggregation tree; where  $n$  is the number of nodes in the network,  $\delta$  is the fanout of any node in the aggregation tree, and  $k$  is the variable. Ideally, we want  $k = 0$ , in the case of SHIA and our protocol  $k = 2$ , which will be explained in the later chapter.

The high level idea of the aggregate commit with verification scheme is that all the nodes in the network send the signature of the message along with the message itself. It sends its certificate if the parent node does not have it already. The parent node verifies all the received signatures from its children. And proceeds with the aggregation process. After aggregation, the parent node can throw away all the signatures from its children and signs the message of its children or it can pass its children's signatures to its parent. The pros and cons of each approach are discussed in the following sections.

## 6.2 Data-Item

We describe structure of the data-item, used in creating the commitment tree for the aggregate commit with verification approach. And differences between the data-item and the label structure of SHIA with rational behind it.

**Definition 6.2.1** *A commitment tree is a binary tree where each vertex has an associated data-item representing the data that is passed on to its parent. The data-items have the following format:*

$$< id, count, value, commitment >$$

Where  $id$  is the unique ID of the node;  $count$  is the number of leaf vertices in the subtree rooted at this vertex;  $value$  is the SUM aggregate computed over all the leaves in the subtree and  $commitment$  is a cryptographic commitment.

We remove the *complement* field from the label structure Defined 5.7.1. We think the complement field is redundant information in the label. The complement field is used by the base station (the querier according to SHIA), before the result checking phase, to verify  $\mathbf{SUM} + \mathbf{COMPLEMENT} = \mathbf{n} \cdot \mathbf{r}$ ; where  $\mathbf{n}$  is the number of nodes in the network,  $\mathbf{r}$  is the upper bound on the allowed sensor readings. We can achieve the same upper bound without the complement field. As the querier knows  $n, r$  and it gets SUM from the root of the aggregation tree. If  $\mathbf{SUM} > \mathbf{n} \cdot \mathbf{r}$ , then the base station knows some node or nodes in the network reported out of range readings.

We include  $id$  of the node in its data-item. SHIA does not have the ID field in their label structure as they do not do internal verification while creating a commitment tree and while distributing off-path values. Also, in the label format ID of the node is hashed in the commitment field after the first aggregation and virtually gets lost. Hence, SHIA can not provide authenticity of the message and is vulnerable to masquerade attacks. We do internal verification while creating the commitment tree and distributing off-path values. So, it is necessary for any aggregate node to know the ID of all the received data-items in its forest, for the verification of the received signatures as shown in the next section.

### 6.3 Signing the Data-Item

During commitment tree generation phase, there is one vertex  $S_0$  for each sensor node  $S$ , which we call the leaf vertex of  $S$ . The data-item for leaf vertex  $S_0$  and associated signature to it is defined as follows:

$$S_0 = < S_{id}, 1, S_{value}, H(N||1||S_{value}) >; \text{Sign}_{S_S}(S_0) \quad (6.1)$$

where  $H$  is a collision resistant hash function,  $S_S$  is the secret key of  $S$ ,  $N$  is the query nonce.

The key difference between the SHIA's approach and our approach is that, in addition to sending the data-item, each sensor node sends the signature of the data-item to its parent. It sends its certificate as well if the parent node does not have it in its cache already. The parent node gets the public key of the child node from its certificate, which is used in decrypting the signature. The parent node verifies all the received signature using its children node's public key. Details of the signing and verification process is shown in Figure 3.1. After doing the verification the parent node proceeds to the aggregation and creating the commitment tree.

### 6.3.1 Bandwidth Analysis

Typical size of the data-item packet is 400 bits. If one uses Elliptic curve cryptography then the size of signature is 500 bits. And the certificate size is 1500 bits. So, at max we have to send additional 2000 bits with the data-item. We think it is worthwhile to send these additional bits. Because of all the security benefits we gain from it. **Note:** The packets size are close approximate to the actual packet size. The actual packet size may differ based on the implementation.

### 6.3.2 Security Benefits

This additional signature allows the parent node to verify that the authenticity of the sensor node and integrity of the received data-item. It allows the sender to have the proof for the sent data-item. And the receiver for the proof for the received data-item, eliminating the repudiation attacks.

## 6.4 Signing the Commitment Payload

We define commitment payload based on the commitment forest Defined in 5.7.2.

**Definition 6.4.1** A *commitment payload* is a set of data-items of the root vertices of the trees in the outgoing commitment forest.

For brevity, we use the term forest, payload instead of commitment forest, commitment payload respectively.

An aggregate node sends an additional signature to its parent, which is a signature of all the data-items in its payload. The signature on the payload assures that an aggregate node sent only the data-items included in the payload signature. It assures the authenticity, non-repudiation, integrity of all the data-items included in the payload. For example, the aggregation tree shown in Figure 6.1, the payload of sensor node  $C$  is show in Figure 6.4. The sensor node  $C$  sends all the data-items in

Fig. 6.1.: Palm Shaped Aggregation Tree

its payload with their signatures to its parent sensor node  $D$ . Furthermore,  $C$  sends the signature of its payload  $\text{Sign}_{S_C}(C_0||B_1)$  to  $D$ .

Fig. 6.2.:  $C$ 's Commitment Payload

$$\begin{aligned}
 B_1 &= \langle B_{id}, 2, B_{1value}, H(N||2||B_{1value}||A_0||B_0) \rangle; \text{Sign}_{S_B}(B_1) \\
 C_0 &= \langle C_{id}, 1, C_{value}, H(N||1||C_{value}) \rangle; \text{Sign}_{S_C}(C_0) \\
 &\quad \text{Sign}_{S_C}(C_0||B_1)
 \end{aligned} \tag{6.2}$$

Signature on the  $C$ 's payload  $\text{Sign}_{S_C}(C_0||B_1)$  assures that the sensor node  $C$  sent only two data-items  $C_0, B_1$  in its payload.

### 6.5 Forwarding the Commitment Payload

The sensor node  $C$  has two data-items  $C_0, B_1$  in its payload as shown in Equation 6.2. It sends the  $\text{Sign}_{S_B}(B_1)$ ,  $\text{Sign}_{S_C}(C_0)$  and  $\text{Sign}_{S_C}(C_0||B_1)$  to its parent node  $D$ . It requires the parent node  $D$  to know the public key of the sensor nodes  $C$  and  $D$ , hence their certificates. Instead of that the sensor node  $C$  can verify the  $\text{Sign}_{S_B}(B_1)$  then remove the old signature and create new signature  $\text{Sign}_{S_C}(B_1)$  signed by itself on the data-item  $B_1$  as shown below:

$$\begin{aligned}
 B_1 &= \langle B_{id}, 2, B_{1value}, H(N||2||B_{1value}||A_0||B_0) \rangle; \text{Sign}_{S_C}(B_1) \\
 C_0 &= \langle C_{id}, 1, C_{value}, H(N||1||C_{value}) \rangle; \text{Sign}_{S_C}(C_0) \\
 &\quad \text{Sign}_{S_C}(C_0||B_1)
 \end{aligned} \tag{6.3}$$

We call these two approaches **Forwarding signatures without resigning the data-items**, **Forwarding signatures with resigning the data-items** as shown in Equations 6.2 and 6.3 respectively .

To give an analogy with the real world application consider the following example. One want to buy a diamond from the local diamond retailer. Diamond is an expensive commodity so the end customer wants to verify its authenticity and integrity before purchasing. Suppose, the diamond was created by the manufacturer in Africa, it was sold to a national wholesaler in the United States. The national wholesaler sells it to the state level reseller and he sells it to the city or county level retailer from whom the customer purchases the commodity.

One approach to verify the authenticity of the commodity is to make each entity in the supply chain to verify all the signatures on the received entity and sign on top of it. And then forward the commodity with all the signatures to the next entity in the supply chain. The next entity repeats the same procedure. Hence, any entity in the supply chain need to verify the signatures of all its descendants in the supply chain. In our example, it means to make the manufacturer from Africa signs the diamond and sells the signed diamond with his certificate. The national level wholesaler in United States verifies the signature from the manufacturer using manufacturer's certificate. Then he adds his signature and certificate, and sells to the state level reseller the diamond signed with two signatures and two certificates. The state level reseller verifies both the signatures on the diamond using the certificates. Then he adds his signature and certificate, and sells to the city level retailer the diamond signed with three signatures and three certificates. The city level retailer does the same thing before selling the diamond to the end customer. In the end, the customer needs to verify all four signatures, using the received certificates.

An alternative approach to verify the authenticity of the commodity is to make each entity in the supply chain verify the signature, throw away the old signature, and then add its own signature on it. It means the next entity in the supply chain need to verify only a single signature. The next entity repeats the same procedure. Hence, any entity in the supply chain need to verify the signature of only its direct peer in the supply chain. In our example, it means to make the manufacturer from Africa signs the diamond and sells the signed diamond with his certificate. The national

level wholesaler in United States verifies the signature from the manufacturer using the manufacturer's certificate. Then he removes the signature of the manufacturer, adds his own signature and certificate, and sells to the state level reseller the diamond signed with one signature and one certificate. The state level reseller verifies only the signature from the wholesaler using the wholesaler's certificate. Then he removes the signature of the wholesaler, adds his own signature and certificate, and sells to the city level retailer the diamond signed with one signature and one certificate. The city level retailer does the same thing before selling the diamond to the end customer. In the end, the customer needs to verify only one signature of the city level retailer using retailer's certificate. This approach requires very few number of certificates overall in the supply chain.

Both the approaches have their pros and cons and the perfect approach depends heavily on the application. The various aspects of both the approaches for sensor nodes are discussed in the following sections.

## 6.6 Forwarding signatures with resigning the data-items

If we throw away the old signatures and resign the data-item with current aggregate node then following is true:

- Each parent needs the certificates of only its direct children.
- Each child needs to know the certificate of its parent only.
- Number of signatures remain the same as previous approach.
- Number of certificates needed in the network is  $O(n)$ ;  $n$  is the number of nodes in the network.
- We do not need the signature of the payload.

Note that we send signatures while distributing off-path values.

## 6.7 Forwarding signatures without resigning the data-items

## 6.8 Commitment Tree Generation

For the given aggregation tree the commitment forest is built as follows. Leaf sensor nodes in the aggregation tree create their leaf vertex by creating data-items and their respective signatures according to Equation 6.1, ?? which they send it to their parent as a payload in the aggregation tree. Each internal sensor node  $I$  in the aggregation tree also creates their leaf vertex and its signature. In addition,  $I$  receives the payload from each of its children which creates the forest for  $I$ . Once  $I$  verifies all the received signatures, it merges all the data-items in its forest with same count value to create its payload. Note that we can determine the height of the commitment tree from the count value.

Suppose  $I$  have to create its payload by merging  $i$  data-items  $D_1, D_2, \dots, D_i$  in its forest. First,  $I$  verifies the received signatures  $Sign(D_1), Sign(D_2), \dots, Sign(D_i)$ . Once verified,  $I$  starts merging the data-items as follows. Let  $c$  be the smallest count value in  $I$ 's forest. The sensor node  $I$  finds two data-items  $D_1, D_2$  in its forest with the same count value  $c$  and merges them into a new data-item with the count of  $c + 1$  as shown in Figure 6.3.

It repeats the process until no two data-items in its forest have the same count value. An example of generating the payload by merging the data-items in the forest for the sensor node  $A$  in Figure 5.2 is illustrated in the following example.

**Example 6.8.1** *The commitment-payload generation process for node  $A$  of Figure 5.2 is shown here.*

Fig. 6.3.:  $A$  has  $B_1, C_1$  in his forest and aggregates those two trees and creates  $A_2$ .

Fig. 6.4.:  $A$  receives  $C_2$  from  $C$ ,  $(B_1, B_0)$  from  $B$ ,  $D_0$  from  $D$  and generates  $A_0$ . The commitment payload received from a given sensor node is indicated by dashed-line box.

$$\begin{aligned}
 A_0 &= \langle A_{id}, 1, A_{value}, H(N||1||A_{value}) \rangle; \text{Sign}_{S_A}(A_0) \\
 D_0 &= \langle D_{id}, 1, D_{value}, H(N||1||D_{value}) \rangle; \text{Sign}_{S_D}(D_0) \\
 B_0 &= \langle B_{id}, 1, B_{value}, H(N||1||B_{value}) \rangle; \text{Sign}_{S_B}(B_0) \\
 B_1 &= \langle B_{id}, 2, B_{value}, H(N||2||B_{value}||E_0||F_0) \rangle; \text{Sign}_{S_B}(B_1) \\
 &\quad \text{Sign}_{S_B}(B_0||B_1), \text{benefits} \\
 C_2 &= \langle C_{id}, 4, C_{value}, H(N||4||C_{value}||H_1||C_1) \rangle; \text{Sign}_{S_C}(C_2)
 \end{aligned} \tag{6.4}$$

Fig. 6.5.: First Merge:  $A_1$  vertex created by A.

$$A_1 = \langle A_{id}, 2, A_{1value}, H(N||2||A_{1value}||A_0||D_0) \rangle; \text{Sign}_{S_A}(A_1) \quad (6.5)$$

where  $A_{1value} = A_{value} + D_{value}$

Fig. 6.6.: Second Merge:  $A_2$  vertex created by A.

$$A_2 = \langle A_{id}, 4, A_{2value}, H(N||4||A_{2value}||B_1||A_1) \rangle; \text{Sign}_{S_A}(A_2) \quad (6.6)$$

where  $A_{2value} = B_{1value} + A_{1value}$

$$A_3 = \langle A_{id}, 8, A_{3value}, H(N||8||A_{3value}||C_2||A_2) \rangle; \text{Sign}_{S_A}(A_3) \quad (6.7)$$

where  $A_{3value} = A_{2value} + C_{2value}$

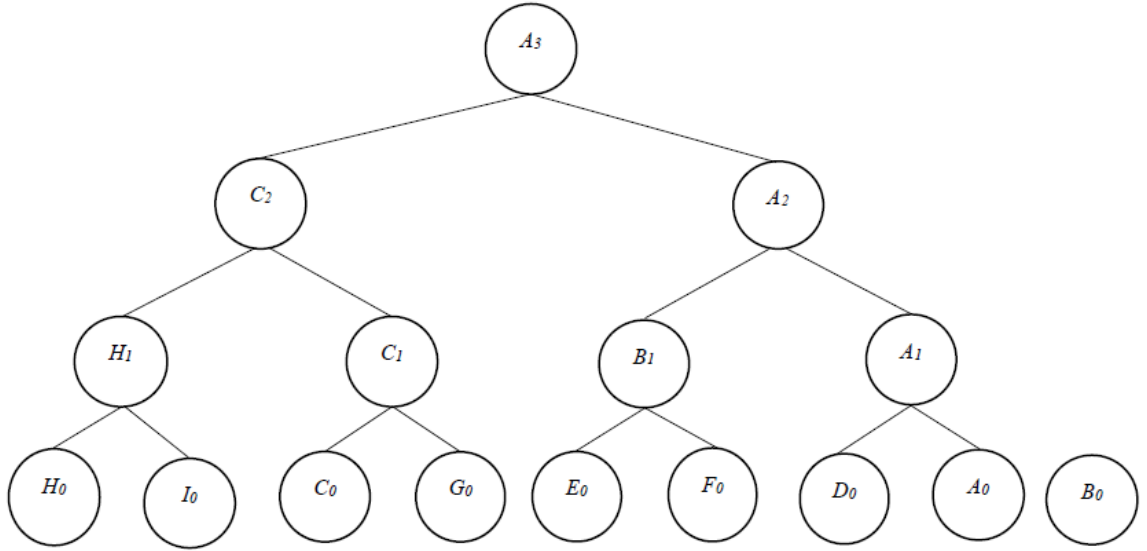

Fig. 6.7.: Third Merge:  $A_3$  vertex created by A.

## 6.9 Bandwidth Analysis

For any given sensor node's forest with  $n$  leaf vertices, has at most  $\log n$  data-items in its payload. It has at most  $(\log n) + 1$  signatures in its payload. The highest possible count value is  $\log n$ , as all the trees are binary.

An intermediate sensor node  $S$  with  $\beta$  descendants in the aggregation tree, has at most  $\log(\beta + 1)$  data-items with their respective  $\log(\beta + 1)$  signatures in its payload.  $S$  might need to send its payload signature  $Sign(S_p)$ . At max,  $S$  has to send a payload with  $\log(\beta + 1)$  data-items and  $\log(\beta + 1) + 1$  signatures to its parent in the aggregation tree.

Hence, sending signatures of the data-items causes  $O(\log \beta)$  bandwidth overhead for each node in the network, where  $\beta$  is the number of descendants of the sensor node.

## 6.10 Result checking

## 6.11 Performance Analysis

In addition to calculating its own data-items, all intermediate sensor nodes with  $\beta$  descendants and  $\zeta$  direct children need to do the following:

- To calculate and verify  $O(\log \beta)$  signatures, creating  $O(\log \beta)$  calculation overhead.
- Needs sufficient memory to cache  $O(\log \beta)$  certificates.
- Needs enough memory to cache  $\Omega(\zeta)$  certificates.

## 6.12 Applications

The signature based aggregation scheme can be applied to do the **voting** in the network. And voting scheme can be used to solve many sensor network problems. For example, voting can be used to design the distributed algorithm for selecting a cluster head or node revocation system. In the voting scheme, following are the major security concerns:

- The aggregate node needs to know that the vote is coming from the legit voter, no other voter is impersonating the vote of the legit voter.
- Only the intended aggregate node should be able to verify the vote.
- The aggregate node should not be able to tamper with the votes.
- The aggregate node needs the proof that it aggregated the verified votes.
- The voter need the proof for which vote it sent to its aggregator.

For example, the base station wants to know the overall vote-count in the network. To do so, all the leaf nodes send their votes and the signature of their votes to their respective aggregate nodes in the network. The aggregate nodes receive votes with

their signatures from all of their children voters. The aggregate nodes verify all the votes and count those votes. Then they forward the count and the signature of that count signed by the aggregate node to their respective parent in the aggregation tree. This process is repeated until the final count and its signature, is sent to the base station by the root of the aggregation tree.

#### **Node power level, Surveillance Application**

## 7. SECURITY ANALYSIS

This chapter describes what does it mean to cheat a secure aggregation algorithm. It depicts detailed examples in which an adversary tries different ways of cheating but fails to do so because of the commitment and signatures.

### 7.1 Introduction

To discuss different ways of cheating first we define the cheating as follows:

**Definition 7.1.1** *A sensor node tampering with the data-item to skew the final aggregate data-item without being detected is consider as **cheating**.*

Because of the way an aggregate commit algorithm works, an aggregate node has the highest power to do the cheating as described in Section 2.5. The aggregate node gains more power to cheat as it climbs up in the aggregation tree hierarchy. An aggregate node can cheat at the following phases:

- During commitment tree generation phase
- During dissemination of off-path phase
- At both phases together (the most powerful attack possible)

We can detect a cheating activity with the help of the commitment field in the data-item as shown in Example 7.1.1. But the commitment field is not enough to detect an adversary. And to identify an adversary we need the help from the base station and the signature infrastructure created in the network.

Fig. 7.1.: Smallest possible commitment tree

### 7.1.1 Assumptions

We make following assumptions for the adversary.

- It can not send an authentication code with NACK message during verification of inclusion phase.
- It does not have the capability to masquerade by reproduce the signatures of any other sensor node.

Without these assumptions, there will be a lot of complainers in the network, creating a lot of traffic in the network. Ultimately, draining the battery levels of the sensor nodes until they die, making some sensor nodes in the network unreachable and potentially causing the denial-of-service attack in the network. Following example shows the different ways an adversary can cheat in the smallest possible commitment tree and how the commitment field in the data-item can help us detect the cheating. And theoretically, all possible commitment trees can be presented as Figure 7.2 for the analysis purpose.

**Example 7.1.1** *Let's say the vertices in the commitment tree of Figure 7.2 have the data-items defined as follows.*

$$\begin{aligned}
 A_0 &= \langle A_{id}, 1, 10, H(N||1||10) \rangle \\
 B_0 &= \langle B_{id}, 1, 20, H(N||1||20) \rangle \\
 C_1 &= \langle C_{id}, 2, 30, H(N||2||30||A_0||B_0) \rangle
 \end{aligned}
 \tag{7.1}$$

Note that we did not include the signatures of these data-items in this example for simplification.

- **No cheating**

$C$  aggregates  $B_0, C_0$  according to the aggregate commit algorithm.

**dissemination of root data-item**

$A, B$  receives  $C_1$  from the base station using authenticated broadcast.

**dissemination of offpath values**

$A$  receives  $B_0$  from  $C$  and vice versa.

**verification of inclusion**

$$\begin{aligned} A \text{ uses } (A_0, B_0) \text{ to calculate } < 2, 30, H(N||2||30||A_0||B_0) > = C_1 \\ B \text{ uses } (A_0, B_0) \text{ to calculate } < 2, 30, H(N||2||30||A_0||B_0) > = C_1 \end{aligned} \quad (7.2)$$

**collection of authentication codes**

$A, B$  sends their authentication codes with ACK messages.

- **Cheating by replacing data-items**

$C$  replaces  $A_0, B_0$  with  $A'_0, B'_0$  and then applies aggregate commit algorithm.

$$\begin{aligned} A'_0 &= < A_{id}, 1, 100, H(N||1||100) > \\ B'_0 &= < B_{id}, 1, 200, H(N||1||200) > \\ C'_1 &= < C_{id}, 2, 300, H(N||2||300||A'_0||B'_0) > \end{aligned} \quad (7.3)$$

**dissemination of root data-item**

$A, B$  receives  $C'_1$  from the base station using authenticated broadcast.

**dissemination of offpath values**

$A$  receives  $B'_0$  from  $C$  and vice versa.

**verification of inclusion**

$$\begin{aligned} A \text{ uses } (A_0, B'_0) \text{ to calculate } < 2, 210, H(N||2||210||A_0||B'_0) > \neq C'_1 \\ B \text{ uses } (A'_0, B_0) \text{ to calculate } < 2, 120, H(N||2||120||A'_0||B_0) > \neq C'_1 \end{aligned} \quad (7.4)$$

**collection of authentication codes**

$A, B$  send their authentication codes with NACK messages.

- **Cheating by tampering with a single data-item**

$C$  replaces  $A_0$  with  $A'_0$  and then applies aggregate commit algorithm.

$$\begin{aligned} A'_0 &= \langle A_{id}, 1, 100, H(N||1||10) \rangle \\ C'_1 &= \langle C_{id}, 2, 120, H(N||2||120||A_0||B'_0) \rangle \end{aligned} \quad (7.5)$$

**dissemination of root data-item**

$A, B$  receives  $C'_1$  from  $C$

**dissemination of offpath values**

$A, B$  receives  $B'_0, A_0$  from  $C$  respectively.

$$\begin{aligned} B'_0 &= \langle B_{id}, 1, 110, H(N||1||110) \rangle \\ A_0 &= \langle A_{id}, 1, 10, H(N||1||10) \rangle \end{aligned} \quad (7.6)$$

**verification of inclusion**

$$\begin{aligned} A \text{ uses } (A_0, B'_0) \text{ to calculate } &\langle 2, 120, H(N||2||120||A_0||B'_0) \rangle = C'_1 \\ B \text{ uses } (A_0, B_0) \text{ to calculate } &\langle 2, 30, H(N||2||30||A_0||B_0) \rangle \neq C'_1 \end{aligned} \quad (7.7)$$

**collection of authentication codes**

$A, B$  send their authentication codes with ACK, NACK message respectively.

- **Cheating by tampering with data-items**

$C$  changes  $A_0, B_0$  to  $A'_0, B'_0$  by changing the value fields and then applies aggregate commit algorithm.

$$\begin{aligned} A'_0 &= \langle A_{id}, 1, 100, H(N||1||10) \rangle \\ B'_0 &= \langle B_{id}, 1, 200, H(N||1||20) \rangle \\ C'_1 &= \langle C_{id}, 2, 300, H(N||2||300||A'_0||B'_0) \rangle \\ C''_1 &= \langle C_{id}, 2, 300, H(N||2||300||A_0||B'_0) \rangle \end{aligned} \quad (7.8)$$

**dissemination of root data-item**

$A, B$  receives either  $C'_1$  or  $C''_1$  from the base station using authenticated broadcast based on what  $C$  send to base station.

**dissemination of offpath values**

$A, B$  receives  $B_0'', A_0''$  from  $C$  respectively.

$$\begin{aligned} B_0'' &= \langle B_{id}, 1, 290, H(N||1||20) \rangle \\ A_0'' &= \langle A_{id}, 1, 280, H(N||1||10) \rangle \end{aligned} \quad (7.9)$$

**verification of inclusion**

$$\begin{aligned} A \text{ uses } (A_0, B_0'') \text{ to calculate } &\langle 2, 300, H(N||2||300||A_0||B_0'') \rangle \neq C'_1 = C''_1 \\ B \text{ uses } (A_0'', B_0) \text{ to calculate } &\langle 2, 300, H(N||2||300||A_0''||B_0) \rangle = C'_1 \neq C''_1 \end{aligned} \quad (7.10)$$

**collection of authentication codes**

$A, B$  send their authentication codes with *NACK* message.

This example shows how the commitment provides **data-integrity** to the data-items. It makes it nearly impossible for an adversary to tamper with the data-items while creating commitment tree and/or while distributing off-path values. This cheating activity can be detected by the commitment filed in the data-item. Later we will show that the adversary can be detected with the provided signature infrastructure.

## 7.2 Possible Cheater Analysis

The following example demonstrates that if the base station knows the commitment tree topology and the complainers in the network then it can guess possible adversaries. Then applies interactive protocol described in Algorithm 1 in the next chapter to identify the adversary. The details on how the base station finds complainers in the network are described in the next chapter. For simplicity, we selected the commitment tree where all the vertices are unique. But this analysis holds true for any commitment tree topology.

**Example 7.2.1** *The base station creates a set  $c = \{c_1, c_2, \dots, c_n\}$  for the complainers based on the protocol described in the Section 8.5. And based on the set  $c$  it creates a set  $a = \{a_1, a_2, \dots, a_n\}$  of the possible adversaries.*

Fig. 7.2.: Smallest possible commitment tree

- If  $c = \{A_0\}$  then  $a = \{I, (B, I), (B, M), (B, I, M)\}$
- If  $c = \{A_0, B_0\}$  then  $a = \{I, M, (I, M), (C, D, O)\}$
- If  $c = \{A_0, B_0, C_0\}$  then  $a = \{(D, O), (I, J), (M, J), (M, J, I)\}$
- If  $c = \{A_0, B_0, C_0, D_0\}$  then  $a = \{M, O, (I, J), (E, F, G, H, O)\}$
- If  $c = \{A_0, B_0, C_0, D_0, E_0\}$  then  $a = \{(O, K), (M, K), (J, I, K), (F, G, H, O)\}$
- If  $c = \{A_0, B_0, C_0, D_0, E_0, F_0\}$  then  $a = \{(O, K), (M, N), (N, O), (J, I, K)\}$
- If  $c = \{A_0, C_0\}$  then  $a = \{(J, I)\}$

## 8. RESULT CHECKING

### 8.1 dissemination final commitment

### 8.2 dissemination of off-path values

Two cases:

- With signatures
- Without signatures

### 8.3 verification of inclusion

### 8.4 collection of authentication codes

### 8.5 verification of authentication codes

The authentication codes for sensor node  $s$ , with either positive or negative acknowledgment message, are defined as follows:

$$MAC_{K_s}(N \parallel ACK) \tag{8.1}$$

$$MAC_{K_s}(N \parallel NACK) \tag{8.2}$$

$K_s$  is the key that  $s$  shares with the base station;  $ACK$ ,  $NACK$  are special messages for positive and negative acknowledgment respectively. The authentication code with  $ACK$  message is sent by the sensor node if it verifies its contribution correctly to the root commitment value during the *verification of inclusion* phase and vice versa.

To verify that every sensor node has sent its authentication code with  $ACK$ , the base station computes the  $\Delta_{ack}$  as follows:

$$\Delta_{ack} = \bigoplus_{i=1}^n MAC_{K_i}(N \parallel ACK) \tag{8.3}$$

The base station can compute  $\Delta_{ack}$  as it knows  $K_s$  for each sensor node  $s$ . Then it compares the computed  $\Delta_{ack}$  with the received root authentication code  $\Delta_{root}$  from the root of the aggregation tree. If those two codes match then it accepts the aggregated value or else it proceeds further to find an adversary.

To detect an adversary, the base station needs to identify which nodes in the aggregation tree sent its authentication codes with *NACK* during the verification of inclusion phase. The node who sent authentication code with *NACK* during the verification of inclusion phase is called a *complainer*. We claim that if there is a single complainer in the aggregation tree during the verification of inclusion phase then the base station can find the complainer in linear time. To find a complainer, the base station computes the complainer code  $c$ .

$$c := \Delta_{root} \oplus \Delta_{ack} \quad (8.4)$$

Then it computes the complainer code  $c_i$  for all node  $i = 1, 2, \dots, n$ .

$$c_i := MAC_{K_i}(N \parallel ACK) \oplus MAC_{K_i}(N \parallel NACK) \quad (8.5)$$

Then it compares  $c$  with all  $c_i$  one at a time. The matching code indicates the complainer node. The base station needs to do  $\binom{n}{1}$  calculations according to Equation 8.5 and same number of comparisons to find a complainer in the aggregation tree. Hence, the base station can find a single complainer in linear time.

**Example 8.5.1** *If there are four nodes  $s_1, s_2, s_3, s_4$  in an aggregation tree and their authentication codes with *ACK*, *NACK* message in the binary format are defined below.*

$$MAC_{K_1}(N \parallel ACK) = (1001)_2 ; \quad MAC_{K_1}(N \parallel NACK) = (1101)_2$$

$$MAC_{K_2}(N \parallel ACK) = (0110)_2 ; \quad MAC_{K_2}(N \parallel NACK) = (1111)_2$$

$$MAC_{K_3}(N \parallel ACK) = (0101)_2 ; \quad MAC_{K_3}(N \parallel NACK) = (0111)_2$$

$$MAC_{K_4}(N \parallel ACK) = (0011)_2 ; \quad MAC_{K_4}(N \parallel NACK) = (1110)_2$$

$$\Delta_{root} = (0100)_2$$

$$\Delta_{ack} = (1101)_2$$

$$c_1 = (0100)_2, c_2 = (1001)_2, c_3 = (0010)_2, c_4 = (1101)_2$$

$$c = (1101)_2 \text{ } c \text{ is equal to } c_4.$$

So, the base station identifies that the  $s_4$  complained, during verification of inclusion phase.

In general, to find  $k$  complainers the base station needs to do  $\binom{n}{k}$  calculations and the same number of comparisons to find  $k$  complainers.

How XOR is negating the contribution of NACK.

$$\begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \\ \hline 1 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 \\ \hline 1 & 0 & 1 & 1 \end{pmatrix}$$

The base station receives the following:

$$\begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \\ \hline 0 & 1 & 0 & 0 \end{pmatrix}$$

The base station does the following:

$$\begin{pmatrix} 1 & 0 & 0 & 1 & | & 0 & 1 & 1 & 0 & | & 0 & 1 & 0 & 1 & | & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & | & 1 & 1 & 1 & 1 & | & 0 & 1 & 1 & 1 & | & 1 & 1 & 1 & 0 \\ \hline 0 & 1 & 0 & 0 & | & 1 & 0 & 0 & 1 & | & 0 & 0 & 1 & 0 & | & 1 & 1 & 0 & 1 \end{pmatrix}$$

$$\begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ \hline 1 & 1 & 0 & 1 \end{pmatrix}$$

And concludes that node 4 is complaining.

## 8.6 Detect an adversary

---

**Algorithm 1** Pseudo algorithm to detect an adversary

---

- 1:  $BS$  identifies all the complainer and creates  $c = \{c_1, c_2, \dots, c_n\}$
  - 2: **for all**  $N \in c$  **do**
  - 3:    $BS$  asks  $N$  to send data-items with its signature, sent during commitment tree generation phase
  - 4:  $BS$  identifies possible adversary based on  $c$  and creates  $a = \{a_1, a_2, \dots, a_n\}$
  - 5: **for all**  $A \in a$  **do**
  - 6:    $BS$  asks  $A$  to send data-items with its signature, received and sent by  $A$  during commitment tree generation phase
  - 7:   If needed  $BS$  asks the parent of  $A$  to send data-items with its signature
  - 8:  $BS$  determines the adversary based on the verification of signatures
- 

**Theorem 8.6.1** *Binary commitment tree is optimal in terms of verification as it requires minimum number of off-path values.*

**Proof** Let us say  $n$  is the number of leaves in the given commitment tree.

$$\log_3(n) = y$$

$$3^y = n$$

$$\log_2(3^y) = \log_2(n)$$

$$y * \log_2(3) = \log_2(n)$$

$$\log_3(n) * \log_2(3) = \log_2(n)$$

$$\log_3(n) = \frac{\log_2(n)}{\log_2(3)}$$

$$2 * \log_3(n) = [2 / \log_2(3)] * \log_2(n) = (1.2618) * \log_2(n)$$

$$2 * \log_3(n) > \log_2(n)$$

For the given binary commitment tree, each leaf vertex needs  $\log_2(n)$  off-path values in the verification phase. The total off-path values needed in the given commitment tree is  $n \cdot \log_2(n)$ .

For the given tertiary commitment tree, each leaf vertex needs  $2 \cdot \log_3(n)$  off-path values in the verification phase. The total off-path values needed in given commitment tree is  $2 \cdot n \cdot \log_3(n)$ .

Hence, in totality the binary commitment tree requires the minimum number of off-path values. ■

**Theorem 8.6.2** [17] *The Aggregate Commit with verification induces  $O(\log^3 n)$  edge congestion. And  $O(\delta \log^3 n)$  node congestion in the aggregation tree.*

**Proof** While creating the commitment tree every sent message is at most  $O(\log n)$  size. And while the off-path value dissemination step is the ■

## 9. NOTES

- Do we hash node's id in the commitment field of its data-item? NO
- Do we send the payload signature in case of Figure 5.4? YES

To do list:

- Meeting:
  - Discuss resigning approach.
  - Do we need Signature of the payload? Yes, for not cutting the tree.
  - value of  $k$  in your work.
  - number of certificates needed in the network?
  - Form-8.
- ch-3: Digital signatures helps authentication, non-repudiation, data integrity
- Cheating: Cheating detection with CT generation.
- Cheating: Cheating detection with off-path distribution.
- Cheating: Cheating detection with both scenarios in place.
- Fix images with Power point.

Signature on the payload is important for signifying not cutting the tree.

Compare number of signatures in both approaches are same but amount of signing is different. Compare number of certificates in both approaches.

Matrix for choice of protocol  
 Number of certificates    Number of signing    Number of signatures    Power consumption

Matrix for different topologies star, palm, binary

Include verification with the protocol.

Savings the BW then make decision with power analysis.

We should meet when what to write?
